

DESCRIPTION**MOTOR CONTROL APPARATUS AND MOTOR CONTROL METHOD****Technical Field**

5 The present invention relates to a motor control apparatus and a motor control method. More specifically the invention pertains to a motor control apparatus that controls a motor, which is mounted on a vehicle and outputs power to a drive shaft linked to drive wheels, as well as to a corresponding
10 motor control method.

Background Art

One proposed motor control apparatus restricts torque output from a motor to a drive shaft, in response to occurrence 15 of a skid due to wheelspin of drive wheels with the torque output from the motor (see, for example, Japanese Patent Laid-Open Gazette No. 10-304514). This motor control apparatus restricts the torque level output from the motor in response to detection of a skid based on an increase in angular 20 acceleration of the drive wheels (that is, a time variation of angular velocity), while canceling the torque restriction of the motor in response to elimination of the skid by the torque restriction.

This prior art motor control apparatus uniformly cancels the torque restriction, regardless of the driver's demand. This may cause the driver to feel uncomfortable and worsen the drivability.

5 The applicant of the present invention has disclosed a vehicle skid control technique that regulates a degree of torque restriction, which is set in response to occurrence of a skid, according to an accelerator opening or a driver's step-on amount of an accelerator pedal and regulates a degree of cancellation
10 of the torque restriction in response to elimination of the skid (see Japanese Patent Laid-Open Gazette No. 2001-295676) .

Disclosure of the Invention

The motor control apparatus and the corresponding motor control method of the invention aim to enhance drivability in skid control of a vehicle. The motor control apparatus and the corresponding motor control method of the invention also aim to prevent an excessive skid of a vehicle while reflecting a driver's acceleration demand in skid control of the vehicle.
15

20 At least part of the above and the other related objects is attained by the motor control apparatus and the corresponding motor control method of the invention having the arrangements discussed below.

A motor control apparatus of the invention controls a motor, which is mounted on a vehicle and outputs power to a drive shaft linked to drive wheels, and includes: a skid detection module that detects a skid due to wheelspin of the drive wheels;

5 a torque restriction control module that, in response to detection of a skid by the skid detection module, sets torque restriction for reduction of the skid and controls the motor under the torque restriction; and a torque restriction cancellation control module that, in response to at least a reducing tendency of the skid, cancels the torque restriction,

10 which is set by the torque restriction control module, to a specific degree corresponding to a variation in driver's accelerator operation, and controls the motor under at least partly cancelled torque restriction.

15 The motor control apparatus of the invention detects a skid due to wheelspin of the drive wheels, sets torque restriction for reducing the skid in response to detection of a skid, and controls the motor under the torque restriction. In response to at least a reducing tendency of the skid, the

20 motor control apparatus cancels the torque restriction to a specific degree corresponding to a variation in driver's accelerator operation, and controls the motor under at least partly cancelled torque restriction. The cancellation of the

torque restriction in response to the reducing tendency of the skid reflects the variation in driver's accelerator operation, that is, the driver's acceleration demand of the vehicle under the condition of occurrence of a skid. This arrangement
5 desirably enhances the drivability in cancellation of the torque restriction, compared with a prior art arrangement that does not reflect the driver's acceleration demand in cancellation of the torque restriction.

In the motor control apparatus of the invention, the
10 variation in driver's accelerator operation may represent a rate of change relative to a reference accelerator operation at a time of detection of a skid by the skid detection module. This arrangement adequately understands the driver's acceleration demand of the vehicle under the condition of
15 occurrence of a skid.

In the motor control apparatus of the invention, the torque restriction cancellation control module may cancel the torque restriction in a stepwise manner with elapse of time. This arrangement desirably lowers the potential for
20 reoccurrence of a skid by cancellation of the torque restriction. In this embodiment of the motor control apparatus, the torque restriction cancellation control module may control the motor with a tendency of increasing a cancellation rate of the torque

restriction with an increase in driver's additional depression of an accelerator pedal as the variation in driver's accelerator operation. This arrangement cancels the torque restriction by a greater cancellation rate corresponding to the driver's 5 acceleration demand. Further, in this embodiment of the motor control apparatus, the torque restriction cancellation control module may control the motor with a tendency of shortening a cancellation time of the torque restriction with an increase in driver's additional depression of an accelerator 10 pedal as the variation in driver's accelerator operation. This arrangement cancels the torque restriction within a shorter cancellation time corresponding to the driver's acceleration demand.

The motor control apparatus of the invention may further 15 include: an angular acceleration measurement module that measures an angular acceleration of either of the drive shaft and a rotating shaft of the motor, and in this embodiment, the skid detection module may detect a skid, based on a variation in measured angular acceleration, and the torque restriction 20 control module, in response to detection of a skid, may change a degree of the torque restriction corresponding to the angular acceleration measured by the angular acceleration measurement module and controls the motor under the changed degree of the

torque restriction. This arrangement effectively sets the torque restriction according to the degree of the skid, which is based on the angular acceleration, so as to reduce the skid.

In the motor control apparatus of the invention, the
5 vehicle may have driven wheels that are driven by the drive wheels, and the motor control apparatus may further include: a drive wheel rotation speed measurement module that measures a rotation speed of the drive wheels; and a driven wheel rotation speed measurement module that measures a rotation speed of the
10 driven wheels. In this embodiment, the skid detection module may detect a skid, based on a rotation speed difference between the rotation speed of the drive wheels measured by the drive wheel rotation speed measurement module and the rotation speed of the driven wheels measured by the driven wheel rotation speed
15 measurement module, and the torque restriction control module, in response to detection of a skid, may change a degree of the torque restriction corresponding to the rotation speed difference and control the motor under the changed degree of the torque restriction. This arrangement effectively sets the
20 torque restriction according to the degree of the skid, which is based on the rotation speed difference between the rotation speed of the drive wheels and the rotation speed of the driven wheels, so as to reduce the skid.

In the motor control apparatus of the invention, the motor control apparatus may further include: a torque re-restriction control module that, in response to detection of another skid by the skid detection module under control of the motor by the

5 torque restriction cancellation control module, sets torque re-restriction for reduction of the another skid and controls the motor under the torque re-restriction. This arrangement effectively reduces another skid occurring under cancellation of the torque restriction corresponding to the variation in

10 driver's accelerator operation. The motor control apparatus of the invention structured in this way may further include: an angular acceleration measurement module that measures an angular acceleration of either of the drive shaft and a rotating shaft of the motor, and in this embodiment, the skid detection

15 module may detect a skid, based on a variation in measured angular acceleration, and the torque re-restriction control module, in response to detection of another skid by the skid detection module, may change a degree of the torque re-restriction corresponding to a peak value of the angular

20 acceleration measured by the angular acceleration measurement module and control the motor under the changed degree of the torque re-restriction. This arrangement effectively re-restricts the torque according to the degree of another skid,

which is based on the peak value of the angular acceleration. The motor control apparatus of the invention may further include: a torque restriction re-cancellation control module that cancels the torque re-restriction set by the torque 5 re-restriction control module after elapse of a preset time period corresponding to a variation in driver's accelerator opening, regardless of state of the another skid, and controls the motor under the cancelled torque re-restriction. This arrangement responds to the driver's acceleration demand of the 10 vehicle, while desirably preventing an excess amount of another skid.

A motor control method of the invention controls a motor, which is mounted on a vehicle and outputs power to a drive shaft linked to drive wheels, and the motor control method include 15 the steps of: (a) detecting a skid due to wheelspin of the drive wheels; (b) in response to detection of a skid by the step (a), setting torque restriction for reduction of the skid and controlling the motor under the torque restriction; and (c) in response to at least a reducing tendency of the skid, canceling 20 the torque restriction, which is set by the step (b), to a specific degree corresponding to a variation in driver's accelerator operation, and controlling the motor under at least partly cancelled torque restriction.

In the motor control method of the invention, the variation in driver's accelerator operation may represent a rate of change relative to a reference accelerator operation at a time of detection of a skid by the step (a).

5 Further, in the motor control method of the invention, the step (c) may cancel the torque restriction in a stepwise manner with elapse of time. In this embodiment of the motor control method, the step (c) may control the motor with a tendency of increasing a cancellation rate of the torque 10 restriction with an increase in driver's additional depression of an accelerator pedal as the variation in driver's accelerator operation. Moreover, in the motor control method of the invention, the step (c) may control the motor with a tendency of shortening a cancellation time of the torque restriction with 15 an increase in driver's additional depression of an accelerator pedal as the variation in driver's accelerator operation.

The technique of the invention is not restricted to the motor control apparatus or the corresponding motor control method discussed above, but may also be actualized by a vehicle 20 equipped with a motor and the motor control apparatus of the invention.

Best Modes of Carrying Out the Invention

Some modes of carrying out the invention are described
below as preferred embodiments. Fig. 1 schematically
20 illustrates the configuration of an electric vehicle 10
equipped with a motor control apparatus 20 in one embodiment
of the invention. As illustrated, the motor control apparatus
20 of the embodiment is constructed to drive and control a motor

12, which uses electric power supplied from a battery 16 via an inverter circuit 14 and outputs power to a drive shaft linked to drive wheels 18a, 18b of the electric vehicle 10. The motor control apparatus 20 includes a rotation angle sensor 22 that

5 measures a rotation angle θ of a rotating shaft of the motor 12, a vehicle speed sensor 24 that measures a driving speed of the vehicle 10, wheel speed sensors 26a, 26b, 28a, and 28b that respectively measure wheel speeds of the drive wheels (front wheels) 18a and 18b and driven wheels (rear wheels) 19a and 19b

10 driven by the drive wheels 18a and 18b, diversity of sensors that detect the driver's various operations (for example, a gearshift position sensor 32 that detects the driver' setting position of a gearshift lever 31, an accelerator pedal position sensor 34 that detects the driver's step-on amount of an accelerator pedal 33 (an accelerator opening), and a brake pedal position sensor 36 that detects the driver's step-on amount of a brake pedal 35 (a brake opening)), and an electronic control unit 40 that controls the respective constituents of the apparatus.

15

20 The motor 12 is, for example, a known synchronous motor generator that functions both as a motor and a generator. The inverter circuit 14 includes multiple switching elements that convert a supply of electric power from the battery 16 into

another form of electric power suitable for actuation of the motor 12. The structures of the motor 12 and the inverter circuit 14 are well known in the art and are not the key part of this invention, thus not being described here in detail.

5 The electronic control unit 40 is constructed as a microprocessor including a CPU 42, a ROM 44 that stores processing programs, a RAM 46 that temporarily stores data, and input and output ports (not shown). The electronic control unit 40 receives, via the input port, the rotation angle θ of the 10 rotating shaft of the motor 12 measured by the rotation angle sensor 22, the vehicle speed V of the vehicle 10 measured by the vehicle speed sensor 24, the wheel speeds V_{f1} and V_{f2} of the drive wheels 18a and 18b and the wheel speeds V_{r1} and V_{r2} 15 of the driven wheels 19a and 19b measured by the wheel speed sensors 26a, 26b, 28a, and 28b, the gearshift position detected by the gearshift position sensor 32, the accelerator opening Acc detected by the accelerator pedal position sensor 34, and the brake opening detected by the brake pedal position sensor 36. The electronic control unit 40 outputs control signals, 20 for example, switching control signals to the switching elements of the inverter circuit 14 to drive and control the motor 12, via the output port.

The description regards the operations of the motor

control apparatus 20 constructed as discussed above, especially
a series of operations of driving and controlling the motor 12
in the event of occurrence of a skid due to wheelspin of the
drive wheels 18a and 18b of the vehicle 10. Fig. 2 is a flowchart
5 showing a motor drive control routine executed by the electronic
control unit 40 in the motor control apparatus 20 of the
embodiment. This control routine is repeatedly executed at
preset time intervals (for example, at every 8 msec).

When the motor drive control routine starts, the CPU 42
10 of the electronic control unit 40 first inputs the accelerator
opening Acc from the accelerator pedal position sensor 34, the
vehicle speed V from the vehicle speed sensor 24, wheel speeds
Vf and Vr from the wheel speed sensors 26a, 26b, 28a, and 28b,
and a motor rotation speed Nm calculated from the rotation angle
15 θ measured by the rotation angle sensor 22 (step S100). In this
embodiment, the wheel speeds Vf and Vr respectively represent
an average of the wheel speeds Vf1 and Vf2 measured by the wheel
speed sensors 26a and 26b and an average of the wheel speeds
Vr1 and Vr2 measured by the wheel speed sensors 28a and 28b.
20 The vehicle speed V is measured by the vehicle speed sensor 24
in this embodiment, but may alternatively be calculated from
the wheel speeds Vf1, Vf2, Vr1, and Vr2 measured by the wheel
speed sensors 26a, 26b, 28a, and 28b.

The CPU 42 then sets a torque demand T_m^* of the motor 12 according to the input accelerator opening Acc and the input vehicle speed V (step S102). A concrete procedure of setting the motor torque demand T_m^* in this embodiment stores in advance 5 variations in motor torque demand T_m^* against the accelerator opening Acc and the vehicle speed V as a map in the ROM 44 and reads the motor torque demand T_m^* corresponding to the given accelerator opening Acc and the given vehicle speed V from the map. One example of this map is shown in Fig. 3.

10 The CPU 42 subsequently calculates an angular acceleration α from the motor rotation speed N_m input at step S100 (step S104). The calculation of the angular acceleration α in this embodiment subtracts a previous rotation speed N_m input in a previous cycle of this routine from a current rotation 15 speed N_m input in the current cycle of this routine (current rotation speed N_m - previous rotation speed N_m). The unit of the angular acceleration α is [rpm / 8 msec] since the execution interval of this routine is 8 msec in this embodiment, where the rotation speed N_m is expressed by the number of rotations 20 per minute [rpm]. Any other suitable unit may be adopted for the angular acceleration α as long as the angular acceleration α is expressible as a time variation of rotation speed. In order to minimize a potential error, the angular acceleration α may

be an average of angular accelerations calculated in a preset number of cycles of this routine (for example, 3).

The CPU 42 determines a skid state of the drive wheels 18a and 18b based on the calculated angular acceleration α (step 5 S106), and executes a required series of control according to the result of the determination (steps S110 to S114), before terminating this motor drive control routine. The determination of no occurrence of a skid (when both a skid occurrence flag F1 and a skid convergence flag F2 described 10 below are set equal to 0) triggers grip-state control (step S110). The determination of the occurrence of a skid (when the flag F1 is set equal to 1 and the flag F2 is set equal to 0) triggers skid occurring state control (step S112). The determination of convergence of a skid (when both the flags F1 15 and F2 are set equal to 1) triggers skid convergence state control (step S114).

The determination of the skid state follows a skid state determination routine shown in Fig. 4. When the skid state determination routine starts, the CPU 42 of the electronic 20 control unit 40 compares the angular acceleration α calculated at step S104 in the control routine of Fig. 2 with a preset threshold value α_{slip} , which suggests the occurrence of a skid due to wheelspin (step S130). When the calculated angular

acceleration α exceeds the preset threshold value α_{slip} , the CPU 42 determines the occurrence of a skid on the wheels 18a and 18b and sets the value '1' to a skid occurrence flag F1 representing the occurrence of a skid (step S132), before 5 exiting from this skid state determination routine. When the calculated angular acceleration α does not exceed the preset threshold value α_{slip} , on the other hand, the CPU 42 determines whether the skid occurrence flag F1 is equal to 1 (step S134). When the skid occurrence flag F1 is equal to 1, the CPU 42 10 subsequently determines whether the calculated angular acceleration α has been kept negative for a preset time period (step S136). In the case of an affirmative answer, the CPU 42 determines convergence of the skid occurring on the drive wheels 18a and 18b and sets the value '1' to a skid convergence flag 15 F2 (step S138), before exiting from this skid state determination routine. In the case of a negative answer, on the other hand, the CPU 42 determines no convergence of the skid and terminates this skid state determination routine. When the calculated angular acceleration α does not exceed the preset 20 threshold value α_{slip} and the skid occurrence flag F1 is not equal to 1, the CPU 42 sets both the skid occurrence flag F1 and the skid convergence flag F2 equal to 0 (step S140) and terminates this skid state determination routine. The

respective controls of the motor 12 according to the values of the skid occurrence flag F1 and the skid convergence flag F2 are described in detail below.

The grip state control is normal drive control of the motor 5 12 and drives and control the motor 12 to ensure output of a torque corresponding to the preset torque demand T_m^* .

The skid occurring state control drives and controls the motor 12 to lower the angular acceleration α , which was increased by the occurrence of a skid, and follows a skid 10 occurring state control routine of Fig. 5. The CPU 42 of the electronic control unit 40 first compares the angular acceleration α with a preset peak value α_{peak} (step S150). When the angular acceleration α exceeds the preset peak value α_{peak} , the peak value α_{peak} is updated to the current value of the 15 angular acceleration α (step S152). The peak value α_{peak} represents a peak of the angular acceleration α increasing due to a skid and is initially set equal to 0. Until the angular acceleration α increases to reach its maximum, the peak value α_{peak} is successively updated to the current value of the 20 angular acceleration α . When the increasing angular acceleration α reaches its maximum, the maximum value of the increasing angular acceleration α is fixed to the peak value α_{peak} . After setting the peak value α_{peak} , the CPU 42 sets a

maximum torque T_{max} as an upper limit of torque output from the motor 12 corresponding to the peak value α_{peak} (step S154). The procedure of this embodiment refers to a map shown in Fig. 6 to set the maximum torque T_{max} . Fig. 6 shows a variation in 5 maximum torque T_{max} against the angular acceleration α . As illustrated in this map, the maximum torque T_{max} decreases with an increase in angular acceleration α . The greater peak value α_{peak} with an increase in angular acceleration α , that is, the heavier skid, sets the smaller value to the maximum torque T_{max} and limits the output torque of the motor 12 to the smaller 10 maximum torque T_{max} .

After setting the maximum torque T_{max} , the motor torque demand T_m^* is compared with the maximum torque T_{max} (step S156). When the motor torque demand T_m^* exceeds the maximum torque T_{max} , 15 the motor torque demand T_m^* is limited to the maximum torque T_{max} (step S158). The CPU 42 then sets the motor torque demand T_m^* to a target torque and drives and controls the motor 12 to output a torque corresponding to the target torque T_m^* (step S160), before exiting from this skid occurring state control 20 routine. The torque output from the motor 12 in the occurrence of a skid is limited to a lower level (that is, the maximum torque T_{max} corresponding to the peak value α_{peak} of the angular acceleration in the map of Fig. 6) for immediate reduction of

the skid. This limitation effectively reduces the skid.

The skid convergence state control drives and controls the motor 12 to restore the limited torque level, when the torque restriction by the skid occurring state control lowers the 5 angular acceleration α and converges the skid. The skid convergence state control follows a skid convergence state control routine of Fig. 7. The CPU 42 of the electronic control unit 40 first inputs a torque restoration limit δ_1 and a torque restriction rate δ_{safe} (both expressed in the same unit [rpm 10 / 8 msec] as the angular acceleration) (step S170).

The torque restoration limit δ_1 is a parameter used to set a degree of restoration from the torque restriction by increasing the maximum torque T_{max} , which has been set in the skid occurring state control described above. The initial 15 value of the torque restoration limit δ_1 is set equal to 0. The torque restoration limit δ_1 is set according to a torque restoration limit δ_1 setting routine shown in Fig. 8 as discussed below. The torque restoration limit δ_1 setting routine of Fig. 8 is executed when the skid occurrence flag F_1 is set from 0 20 to 1 (that is, when the calculated angular acceleration α exceeds the preset threshold value α_{slip}) at step S132 in the skid state determination routine of Fig. 4. The CPU 42 of the electronic control unit 40 first inputs the motor rotation speed

Nm calculated from the rotation angle θ measured by the rotation angle sensor 22 (step S200) and calculates the angular acceleration α of the motor 12 from the input motor rotation speed Nm (step S202). The CPU 42 then integrates the angular acceleration α to give a time integration α_{int} thereof over an integration interval since the angular acceleration α exceeded the preset threshold value α_{slip} (step S204). In this embodiment, the time integration α_{int} of the angular acceleration α is given by Equation (1) below, where Δt denotes 5 a time interval of the repeated execution of steps S200 to S204 as described below and is set equal to 8 msec in this embodiment:

10

$$\alpha_{int} \leftarrow \alpha_{int} + (\alpha - \alpha_{slip}) \cdot \Delta t \quad (1)$$

15 The processing of steps S200 to S204 is repeated until the angular acceleration α decreases below the preset threshold value α_{slip} (step S196). Namely the integration interval is between the time point when the angular acceleration α exceeds the threshold value α_{slip} and the time point when the angular 20 acceleration α decreases below the threshold value α_{slip} . The torque restoration limit δ_1 is set by multiplying the time integration α_{int} by a predetermined coefficient k_1 (step S208). The torque restoration limit δ_1 setting routine is here

terminated. This routine calculates the torque restoration limit δ_1 by multiplication of the predetermined coefficient k_1 . One modified procedure may prepare in advance a map representing a variation in torque restoration limit δ_1 against the time integration α_{int} and read the torque restoration limit δ_1 corresponding to the given time integration α_{int} from the map. This routine calculates the torque restoration limit δ_1 from the time integration of the angular acceleration α . Another modified procedure may set the torque restoration limit δ_1 based on a peak value of the angular acceleration α in the skid occurring state (that is, the value of the angular acceleration α when the time integration $d\alpha/dt$ of the angular acceleration α is approximate to zero). Still another modified procedure may set a fixed value to the torque restoration limit δ_1 , irrespective of the angular acceleration α . The concrete process of setting the torque restoration limit δ_1 writes the value of the torque restoration limit δ_1 into a specific area of the RAM 46.

The torque restriction rate δ_{safe} is a parameter set to reduce another skid, which occurs during the repeated execution of the skid convergence state control routine of Fig. 7. The initial value of the torque restriction rate δ_{safe} is equal to 0. The torque restriction rate δ_{safe} is described in detail

later. As a matter of convenience, the following description regards the skid convergence state control routine of Fig. 7 first on the assumption that no other skid occurs (that is, when the input torque restriction rate δ_2 is equal to 0) and then 5 on the assumption that another skid occurs.

After input of the torque restoration limit δ_1 , the CPU 42 inputs a cancellation request of canceling the torque restoration limit δ_1 if any (step S172) and determines whether the cancellation request has been entered (step S174). This 10 process determines whether a cancellation request has been input to cancel the torque restoration limit δ_1 as the parameter used to set the maximum torque T_{max} . The concrete procedure of inputting a cancellation request reads out the cancellation request, which was written in a predetermined area in the RAM 15 46 according to a torque restoration limit δ_1 cancellation routine of Fig. 9 as discussed below. This torque restoration limit δ_1 cancellation routine is executed repeatedly at preset time intervals (for example, at every 8 msec) during execution 20 of the skid convergence state control routine of Fig. 7 (while the skid convergence flag F_2 is fixed to the value 1).

When the torque restoration limit δ_1 cancellation routine starts, the CPU 42 of the electronic control unit 40 first inputs a skid-state accelerator opening Acc_{slip} and the accelerator

opening Acc (step S210). The skid-state accelerator opening Accslip represents an accelerator opening at the time of the occurrence of a skid. In a more concrete definition, the skid-state accelerator opening Accslip is an accelerator opening detected by the accelerator pedal position sensor 34 when the skid occurrence flag F1 is set from 0 to 1. In this embodiment, the concrete procedure of inputting the skid-state accelerator opening Accslip reads out the accelerator opening, which was detected by the accelerator pedal position sensor 34 at the time of the occurrence of a skid and was written into a predetermined area in the RAM 46. The CPU 42 subsequently subtracts the input skid-state accelerator opening Accslip from the input accelerator opening Acc to calculate an additional accelerator depression Δ Acc ($=$ Acc - Accslip) since the occurrence of the skid (step S212). The CPU 42 sets a cancellation time t of the torque restoration limit δ 1, based on the calculated additional accelerator depression Δ Acc and the input skid-state accelerator opening Accslip (step S214). A concrete procedure of setting the cancellation time t of the torque restoration limit δ 1 in this embodiment stores in advance variations in cancellation time t against the additional accelerator depression Δ Acc and the skid-state accelerator opening Accslip as a map in the ROM 44 and reads the cancellation

time t corresponding to the given additional accelerator depression ΔAcc and the given skid-state accelerator opening Accslip from the map. One example of this map is shown in Fig. 10. As shown in Fig. 10, a shorter time period is set to the cancellation time t with an increase in additional accelerator depression ΔAcc . The greater additional accelerator depression ΔAcc suggests that the driver demands a higher acceleration. Setting the shorter cancellation time t enables the torque restriction with the torque restoration limit δ_1 to be cancelled in a shorter time period, in response to the driver's high acceleration demand. After setting the cancellation time t , the CPU 42 waits until elapse of the set cancellation time t (step S216). When the cancellation time t has elapsed, the CPU 42 subsequently sets a cancellation increment D_1 of a cancellation rate $\Delta\delta_1$ for canceling the torque restoration limit δ_1 , based on the calculated additional accelerator depression ΔAcc and the input skid-state accelerator opening Accslip (step S218). The CPU 42 then increments the cancellation rate $\Delta\delta_1$ by the set cancellation increment D_1 to update the cancellation rate $\Delta\delta_1$ (step S219) and exits from this torque restoration limit δ_1 cancellation routine. A concrete procedure of setting the cancellation increment D_1 in this embodiment stores in advance variations

in cancellation increment D1 against the additional accelerator depression ΔAcc and the skid-state accelerator opening Accslip as a map in the ROM 44 and reads the cancellation increment D1 corresponding to the given additional accelerator depression 5 ΔAcc and the given skid-state accelerator opening Accslip from the map. One example of this map is shown in Fig. 11. As shown in Fig. 11, a greater value is set to the cancellation increment D1 with an increase in additional accelerator depression ΔAcc . The greater additional accelerator depression ΔAcc suggests 10 that the driver demands a higher acceleration. Setting the greater cancellation increment D1 enables the torque restriction with the torque restoration limit δ_1 to be cancelled by a greater degree, in response to the driver's high acceleration demand. The concrete process of setting the 15 cancellation rate $\Delta\delta_1$ writes the value of the cancellation rate $\Delta\delta_1$ into a specific area of the RAM 46.

Referring back to the routine of Fig. 7, in the event of detection of a cancellation request, the CPU 42 subtracts the cancellation rate $\Delta\delta_1$ from the torque restoration limit δ_1 , 20 which is input at step S170, to cancel the torque restoration limit δ_1 (step S176). In the event of no detection of a cancellation request, on the other hand, the torque restoration limit δ_1 is not cancelled. The torque restoration limit δ_1 is

not cancelled until elapse of the cancellation time t at step S216 in the routine of Fig. 9 after the start of the skid convergence state control routine. The angular acceleration α calculated at step S104 in the routine of Fig. 2 is then 5 compared with the sum of the torque restoration limit δ_1 and the torque restriction rate δ_{safe} (step S178). In this cycle, it is assumed that no skid reoccurs. The torque restriction rate δ_{safe} is thus equal to 0, and the angular acceleration α is not greater than the sum of the torque restoration limit δ_1 10 and the torque restriction rate δ_{safe} ($= 0$). The CPU 42 accordingly refers to the map of Fig. 6 and sets the maximum torque T_{max} as an upper limit of torque output from the motor 12 corresponding to the torque restoration limit δ_1 (step S180).

After setting the maximum torque T_{max} , the motor torque 15 demand T_m^* is compared with the preset maximum torque T_{max} (step S184). When the motor torque demand T_m^* exceeds the maximum torque T_{max} , the motor torque demand T_m^* is limited to the maximum torque T_{max} (step S186). The CPU 42 then sets the motor torque demand T_m^* to a target torque and drives and controls 20 the motor 12 to output a torque corresponding to the target torque T_m^* (step S188). The torque control of the motor 12 based on the torque restoration limit δ_1 , which is set corresponding to the time integration of the angular acceleration α , ensures

restoration of the restricted torque to an adequate level in response to convergence of a skid according to the current skid state. Under the condition of a large time integration of the angular acceleration α , which suggests a high potential for 5 occurrence of another skid, the torque restoration level is set low in response to convergence of a skid. Under the condition of a small time integration of the angular acceleration α , which suggests a low potential for occurrence of another skid, on the contrary, the torque restoration level is set high to 10 effectively prevent the occurrence of another skid without excessive torque restriction. After the drive control of the motor 12, the CPU 42 determines whether the torque restoration limit δ_1 is not higher than 0, that is, whether the torque restoration limit δ_1 is completely cancelled (step S190). In 15 the case of complete cancellation, both the skid occurrence flag F1 and the skid convergence flag F2 are reset to zero (step S192). The program then terminates the skid convergence state control routine.

The above description regards the skid convergence state 20 control on the assumption of no reoccurrence of a skid. The following description is on the assumption of reoccurrence of a skid during the repeated execution of the skid convergence state control routine. In the event of reoccurrence of a skid,

the torque restriction is implemented again with the setting of the torque restriction rate δ_{safe} . The torque restriction rate δ_{safe} is set according to a torque restriction rate δ_{safe} setting and cancellation routine shown in Fig. 12. This routine

5 is executed repeatedly at preset time intervals (for example, at every 8 msec) during the repeated execution of the skid convergence state control routine of Fig. 7, that is, for a time period between the time of setting the skid convergence flag F2 to 1 and the time of resetting the skid convergence flag F2

10 to 0.

When the torque restriction rate δ_{safe} setting and cancellation routine starts, the CPU 42 of the electronic control unit 40 first inputs the rotation speed N_m of the motor 12 (step S220) and calculates the angular acceleration α from the input rotation speed N_m (step S222). The CPU 42 then determines whether the calculated angular acceleration α exceeds the preset threshold value α_{slip} , that is, detects reoccurrence or non-reoccurrence of a skid (step S224). In response to detection of no reoccurrence of a skid, the CPU 42

15 immediately exits from this routine without any further processing. In response to detection of reoccurrence of a skid, on the other hand, the CPU 42 subsequently determines whether a differential $d\alpha/dt$ of the angular acceleration α is close

to 0, that is, whether the angular acceleration α has reached a peak (step S226). When it is determined that the angular acceleration α has reached a peak, the current value of the angular acceleration α is set to a peak value α_{peak} (step S228).

- 5 When it is determined that the angular acceleration α has not yet reached a peak, on the other hand, the CPU 42 immediately exits from this routine without any further processing.

The CPU 42 then sets the torque restriction rate δ_{safe} for reduction of the reoccurring skid, based on the peak value 10 α_{peak} (step S230). A concrete procedure of setting the torque restriction rate δ_{safe} in this embodiment stores in advance a variation in torque restriction rate δ_{safe} against the peak value α_{peak} as a map in the ROM 44 and reads the torque restriction rate δ_{safe} corresponding to the given peak value 15 α_{peak} . One example of this map is shown in Fig. 13. As shown in Fig. 13, this map sets a greater value to the torque restriction rate δ_{safe} with an increase in peak value α_{peak} of the angular acceleration α . The torque restriction rate δ_{safe} is set basically to reduce another skid, which is caused by 20 forced cancellation of the torque restoration rate δ_1 in response to the driver's additional depression of the accelerator pedal 33. The procedure of this embodiment regulates the torque restriction rate δ_{safe} to a sufficient

value for effectively preventing an excess skid of the drive wheels 18a and 18b, which may lead to an unstable state of the vehicle 10.

After setting the torque restriction rate δ_{safe} , the CPU 42 inputs the skid-state accelerator opening Accslip and the accelerator opening Acc (step S232) and calculates the additional accelerator depression Δ_{Acc} ($= Acc - Accslip$) (step S234). The CPU 42 sets a cancellation time t of the torque restriction rate δ_{safe} , based on the calculated additional accelerator depression Δ_{Acc} and the input skid-state accelerator opening Accslip (step S236) and waits until elapse of the set cancellation time t (step S238). A map similar to the map of Fig. 10 used for the processing of step S214 in the torque restoration limit δ_1 cancellation routine of Fig. 9 is basically used to set the cancellation time t . Since the torque restriction rate δ_{safe} is set to prevent an excess skid, it is desirable that the cancellation time t of the torque restriction rate δ_{safe} is shorter than the cancellation time t of the torque restoration limit δ_1 . After elapse of the set cancellation time t , the CPU 42 fully cancels the torque restriction rate δ_{safe} (step S240) and exits from this routine. This procedure cancels the torque restriction rate δ_{safe} all at once. One modified procedure may gradually cancel the torque restriction rate

δ_{safe} with elapse of time. The concrete process of setting and canceling the torque restriction rate δ_{safe} writes the value of the torque restriction rate δ_{safe} into a specific area of the RAM 46. The value of the torque restriction rate δ_{safe} written in the specific area of the RAM 46 is read to be processed in the skid convergence state control routine of Fig. 7. The flow of the routine of Fig. 7 in response to detection of reoccurrence of a skid is described below, while description of the overlapped portion with the flow in response to detection of no reoccurrence of a skid is omitted.

In the event of reoccurrence of a skid, the skid convergence state control routine of Fig. 7 is executed for a time period between the time of setting the torque restriction rate δ_{safe} and the time of canceling the torque restriction rate δ_{safe} . The CPU 42 inputs the set torque restriction rate δ_{safe} (step S170) and sets the maximum torque T_{max} , based on the sum of the torque restoration limit δ_1 and the torque restriction rate δ_{safe} ($\delta_1 + \delta_{safe}$) (step S182). In this skid reoccurring state, the driver's additional depression of the accelerator pedal 33 partly cancels the torque restoration limit δ_1 , and the motor 12 is controlled with the maximum torque T_{max} , which has been set only based on the torque restoration limit δ_1 . The control procedure accordingly refers to the map of Fig. 6 and

sets the maximum torque T_{max} corresponding to the sum of the torque restoration limit δ_1 and the torque restriction rate δ_{safe} and restricts the torque output from the motor 12. This effectively prevents reoccurrence of an excess skid. The 5 maximum torque T_{max} is set in this manner (step S180) in the case of reoccurrence of a relatively light skid when the angular acceleration α is not greater than the sum of the torque restoration limit δ_1 and the torque restriction rate δ_{safe} at step S178 in Fig. 7. In the case of reoccurrence of a relatively 10 heavy skid when the angular acceleration α is greater than the sum of the torque restoration limit δ_1 and the torque restriction rate δ_{safe} , the control procedure sets the maximum torque T_{max} based on the sum of the torque restoration limit δ_1 , the torque restriction rate δ_{safe} , and the angular acceleration α ($\delta_1 +$ 15 $\delta_{safe} + \alpha$) (step S182) and controls the operation of the motor 12 with the more restricted maximum torque T_{max} . One modified procedure may set the maximum torque T_{max} based on the sum of the torque restoration limit δ_1 and the torque restriction rate δ_{safe} , regardless of the magnitude of a reoccurring skid.

20 Fig. 14 shows a process of setting the maximum torque T_{m^*} . In response to detection of a skid when the angular acceleration α of the rotating shaft of the motor 12 exceeds the preset threshold value α_{slip} , the control procedure gradually

decreases the maximum torque T_{max} with a variation in angular acceleration α according to the map of Fig. 6. When the angular acceleration α reaches a peak, the torque level is restricted to the maximum torque T_{max} (= value T_1) corresponding to the 5 peak value α_{peak} (see Fig. 14(a)). The maximum torque T_{max} is kept to the value T_1 until determination of convergence of the skid based on a negative level of the angular acceleration α . In response to determination of convergence of the skid, the torque level is restored to the maximum torque T_{max} (= value 10 T_2) corresponding to the torque restoration limit δ_1 , which is set according to the time integration of the angular acceleration α (that is, the skid state), irrespective of the current value of the angular acceleration α (see Fig. 14(b)). The limitation of torque restoration with the torque 15 restoration limit δ_1 effectively prevents reoccurrence of a skid. After elapse of the preset cancellation time according to the driver's additional depression ΔAcc of the accelerator pedal 33, the torque restoration limit δ_1 is cancelled by the cancellation rate corresponding to the additional accelerator 20 depression ΔAcc . The torque level is then restored to the maximum torque T_{max} (= value T_3) corresponding to the updated torque restoration limit δ_1 (see Fig. 14(c)). In the event of reoccurrence of a skid due to the torque restoration, the torque

level is restricted again to the maximum torque T_{max} (= value T4) corresponding to the sum of the updated torque restoration limit δ_1 and the peak value α_{peak} of the angular acceleration α increasing in the skid reoccurring state (see Fig. 14(d)).

- 5 In this state, the torque restriction rate δ_{safe} is set corresponding to the peak value α_{peak} of the angular acceleration α . Even in the event of a decrease in angular acceleration α due to another torque restriction, the torque restoration level is limited again to the maximum torque T_{max}
- 10 (= value T5) corresponding to the sum of the torque restoration limit δ_1 and the torque restriction rate δ_{safe} (see Fig. 14(e)). The torque restriction rate δ_{safe} is cancelled according to the additional accelerator depression ΔAcc after elapse of the preset cancellation time. The torque level is accordingly
- 15 restored to the maximum torque T_{max} (= value T6) corresponding to only the torque restoration limit δ_1 (see Fig. 14(f)).

As described above, the motor control apparatus 20 of the embodiment restricts the torque output from the motor 12 in response to the occurrence of a skid due to wheelspin of the drive wheels 18a and 18b. In the event of reduction of the skid, the motor control apparatus 20 varies the degree of cancellation of the torque restriction (the cancellation rate and the cancellation time) according to the driver's additional

depression ΔAcc of the accelerator pedal 33. The control procedure of this embodiment sets a greater value to the cancellation rate of the torque restriction and a smaller value to the cancellation time with an increase in additional depression ΔAcc of the accelerator pedal 33. Such setting ensures a certain level of response to the driver's acceleration demand, while effectively reducing the skid of the drive wheels 18a and 18b. This arrangement enhances the drivability in the skid control. In the event of reoccurrence of a skid by cancellation of the torque restriction in response to the driver's additional depression of the accelerator pedal 33, the control procedure controls the motor 12 to prevent an excess level of the reoccurring skid. This arrangement thus makes the driver feel the reoccurrence of a skid and release the accelerator pedal 33, while preventing the excess level of the reoccurring skid, which may lead to the unstable state of the vehicle 10.

In the event of reoccurrence of a skid, that is, when the angular acceleration α exceeds the preset threshold value α_{slip} again during repeated execution of the skid convergence state control routine of Fig. 7, the motor control apparatus 20 of the embodiment sets the torque restriction rate δ_{safe} according to the peak value α_{peak} of the angular acceleration α and

restricts the torque level again with the set torque restriction rate δ_{safe} to prevent an excess level of the reoccurring skid. One modified procedure may alternatively execute the skid occurring state control routine of Fig. 5 in response to 5 reoccurrence of a skid. This modified procedure resets the skid convergence flag F2 from 1 to 0 when it is determined at step S130 that the angular acceleration α exceeds the preset threshold value α_{slip} in the skid state determination routine of Fig. 4. This triggers the skid occurring state control 10 routine, instead of the skid convergence state control routine, since the skid occurrence flag F1 is equal to 1 and the skid convergence flag F2 is equal to 0. This modified procedure naturally does not require the series of processing with respect to the torque restriction rate δ_{safe} .

15 A motor control apparatus of a second embodiment is discussed below. The motor control apparatus of the second embodiment has the same hardware configuration as that of the motor control apparatus 20 of the first embodiment. The only difference is series of processing executed by the electronic 20 control unit. The hardware configuration of the motor control apparatus of the second embodiment is thus not specifically described here. The motor control apparatus 20 of the first embodiment detects a skid based on a variation in angular

acceleration α and controls the operation of the motor 12 in response to detection of the skid. The motor control apparatus of the second embodiment, on the other hand, detects a skid based on a variation in difference between the wheel speed V_f of the 5 drive wheels and the wheel speed V_r of the driven wheels (that is, wheel speed difference ΔV) and controls the operation of the motor in response to detection of the skid. Determination of the skid state based on the wheel speed difference ΔV follows a skid state determination routine shown in Fig. 15.

When the skid state determination routine of Fig. 15 starts, the CPU of the electronic control unit first determines whether the wheel speed difference ΔV exceeds a preset threshold value V_{slip} (step S270). When the wheel speed difference ΔV exceeds the preset threshold value V_{slip} , the CPU detects the 15 occurrence of a skid and sets a skid occurrence flag F3 to 1 (step S272) and resets a skid convergence flag F4 to 0 (step S273), before exiting from this routine. When the wheel speed difference ΔV does not exceed the preset threshold value V_{slip} , on the other hand, the CPU subsequently determines whether the 20 skid occurrence flag F3 is equal to 1 (step S274). When the skid occurrence flag F3 is equal to 1, the CPU determines convergence of the skid and sets the skid convergence flag F4 to 1 (step S276), before exiting from this routine. When the

skid occurrence flag F3 is not equal to 1, on the contrary, the CPU resets both the flags F3 and F4 to 0 (step S278) and terminates this routine.

The motor control procedure based on the determined skid state executes grip state control when both the flags F3 and F4 are equal to 0, skid occurring state control when the flag F3 is equal to 1 and the flag F4 is equal to 0, and skid convergence state control when both the flags F3 and F4 are equal to 1. These controls are described in detail. The grip state control is identical with the grip state control executed by the motor control apparatus 20 of the first embodiment and is thus not specifically described here.

The skid occurring state control drives and controls the motor to lower the wheel speed difference ΔV , which was increased by the occurrence of a skid, and follows a skid occurring state control routine of Fig. 16. When the skid occurring state control routine starts, the CPU of the electronic control unit first inputs a torque restriction rate δ_2 (step S260). The torque restriction rate δ_2 is a parameter used to set the maximum torque T_{max} of the motor for elimination of a skid. The torque restriction rate δ_2 is set according to a torque restriction rate δ_2 setting routine shown in Fig. 17 as discussed below. The torque restriction rate δ_2 setting

routine of Fig. 17 is executed repeatedly at preset time intervals (for example, at every 8 msec) for a time period between the time of setting the skid occurrence flag F3 from 0 to 1 at step S272 in the skid state determination routine of 5 Fig. 15 and the time of setting the skid convergence flag F4 from 0 to 1. The torque restriction rate δ_2 setting routine first inputs the wheel speeds V_f and V_r (step S290), calculates the wheel speed difference ΔV as a difference between the input 10 wheel speeds V_f and V_r (step S292), and integrates the calculated wheel speed difference ΔV to give a time integration V_{int} thereof over an integration interval since the wheel speed difference ΔV exceeded the preset threshold value V_{slip} (step S294). In this embodiment, the time integration V_{int} of the 15 wheel speed difference ΔV is given by Equation (2) below, where Δt denotes the execution time interval of this routine:

$$V_{int} \leftarrow V_{int} + (\Delta V - V_{slip}) \cdot \Delta t \quad (2)$$

The torque restriction rate δ_2 is set by multiplying the 20 time integration V_{int} of the wheel speed difference ΔV by a predetermined coefficient k_2 (step S296). The torque restriction rate δ_2 setting routine is here terminated. This routine calculates the torque restriction rate δ_2 by

multiplication of the predetermined coefficient k_2 . One modified procedure may prepare in advance a map representing a variation in torque restriction rate δ_2 against the time integration V_{int} and read the torque restriction rate δ_2 corresponding to the given time integration V_{int} from the map.

5 The set torque restriction rate δ_2 is successively written into a specific area of the RAM 46 to be updated and is input in the routine of Fig. 16. The procedure of this embodiment sets the torque restriction rate δ_2 corresponding to the time integration of the wheel speed difference ΔV . The torque restriction rate δ_2 may otherwise be set corresponding to the value of the wheel speed difference ΔV or may be fixed to a preset value regardless of the value of the wheel speed difference ΔV .

Referring back to the routine of Fig. 16, after input of
15 the torque restriction rate δ_2 , the maximum torque T_{max} as the upper limit of torque output from the motor 12 is set corresponding to the input torque restriction rate δ_2 by referring to the map of Fig. 6 (step S282). After setting the maximum torque T_{max} , a motor torque demand T_m^* is compared with
20 the maximum torque T_{max} (step S284). When the motor torque demand T_m^* exceeds the maximum torque T_{max} , the motor torque demand T_m^* is limited to the maximum torque T_{max} (step S286). The CPU then sets the motor torque demand T_m^* to a target torque

and drives and controls the motor 12 to output a torque corresponding to the target torque T_m^* (step S288), before exiting from this skid occurring state control routine. The torque output from the motor 12 in the occurrence of a skid is
5 limited to a lower level (that is, the maximum torque T_{max} corresponding to the torque restriction rate δ_2 [rpm / 8 msec] in the map of Fig. 6) for immediate reduction of the skid. This limitation effectively reduces the skid.

The skid convergence state control drives and controls
10 the motor to restore the torque level limited in response to the decreasing wheel speed difference ΔV by the skid occurring state control, and follows a skid convergence state control routine of Fig. 18. When the skid convergence state control routine starts, the CPU of the electronic control unit first
15 inputs the last setting of the torque restriction rate δ_2 , which has been set in the last cycle of the repeatedly executed torque restriction rate δ_2 setting routine of Fig. 17 (that is, immediately before the skid convergence flag F4 is set from 0 to 1) (step S300). The CPU 42 receives a cancellation request
20 of the input torque restriction rate δ_2 if any (step S302) and determines whether the cancellation request has been entered (step S304). The cancellation request of the torque restriction rate δ_2 is entered according to a torque restriction

rate δ_2 cancellation routine of Fig. 19. This torque restriction rate δ_2 cancellation routine is basically similar to the torque restoration limit δ_1 cancellation routine of Fig. 9 and is executed repeatedly at preset time intervals (for example, at every 8 msec) during execution of the skid convergence state control routine of Fig. 18. The torque restriction rate δ_2 cancellation routine first inputs the skid-state accelerator opening Accslip and the accelerator opening Acc (step S320), calculates their difference as the additional accelerator depression ΔAcc (step S322), and sets a cancellation time t of the torque restriction rate δ_2 , based on the calculated additional accelerator depression ΔAcc and the input skid-state accelerator opening Accslip (step S324). The cancellation time t is set according to a map having the similar characteristics to those of the map of Fig. 10. After setting the cancellation time t , the routine waits until elapse of the set cancellation time t (step S326). When the cancellation time t has elapsed, the routine subsequently sets a cancellation increment D_2 of a cancellation rate $\Delta\delta_2$ for canceling the torque restriction rate δ_2 , based on the calculated additional accelerator depression ΔAcc and the input skid-state accelerator opening Accslip (step S328). The routine then increments the cancellation rate $\Delta\delta_2$ by the set

cancellation increment D2 to update the cancellation rate $\Delta\delta_2$ (step S330) and is terminated. The cancellation increment D2 is set according to a map having the similar characteristics to those of the map of Fig. 11. The cancellation rate $\Delta\delta_2$ is 5 successively written into a specific area of the RAM 46 to be updated and is subjected to the processing routine of Fig. 18.

Referring back to the skid convergence state control routine of Fig. 18, in the event of detection of a cancellation request (that is, when the cancellation rate $\Delta\delta_2$ is not equal 10 to 0), the CPU subtracts the cancellation rate $\Delta\delta_2$ from the torque restriction rate δ_2 , which is input at step S230, to cancel the torque restriction rate δ_2 (step S306). In the event of no detection of a cancellation request, on the other hand, the torque restriction rate δ_2 is not cancelled. The torque 15 restriction rate δ_2 is not cancelled until elapse of the cancellation time t at step S326 in the routine of Fig. 19 after the start of the skid convergence state control routine. The CPU then refers to the map of Fig. 6 and sets the maximum torque Tmax as an upper limit of torque output from the motor 12 corresponding to the torque restriction rate δ_2 (step S308). After setting the maximum torque Tmax, the motor torque demand Tm* is compared with the preset maximum torque Tmax (step S310). When the motor torque demand Tm* exceeds the maximum torque Tmax,

the motor torque demand T_{m^*} is limited to the maximum torque

T_{max} (step S312). The CPU then sets the motor torque demand

T_{m^*} to a target torque and drives and controls the motor 12 to

output a torque corresponding to the target torque T_{m^*} (step

5 S314). The CPU subsequently determines whether the torque

restriction rate δ_2 is not higher than 0, that is, whether the

torque restriction rate δ_2 is completely cancelled (step S316).

In the case of complete cancellation, both the skid occurrence

flag F3 and the skid convergence flag F4 are reset to zero (step

10 S318). The skid convergence state control routine is here

terminated. In the event of reoccurrence of a skid (when the

wheel speed difference ΔV exceeds again the preset threshold

value V_{slip}) during execution of the skid convergence state

control routine of Fig. 18 after convergence of a skid (after

15 the wheel speed difference ΔV becomes lower than the preset

threshold value V_{slip}), the skid convergence flag F4 is reset

from 1 to 0 at step S273 in the skid state determination routine

of Fig. 15. This triggers the skid occurring state control

routine of Fig. 18 to reduce the reoccurring skid.

20 Fig. 20 shows a process of setting the maximum torque T_{max} .

As shown in Fig. 20, in response to detection of a skid when

the wheel speed difference ΔV exceeds the preset threshold value

V_{slip} , the control procedure gradually increases the torque

restriction rate δ_2 regardless of the angular acceleration α until the wheel speed difference ΔV becomes lower than the preset threshold value V_{slip} . With the increase in torque restriction rate δ_2 , the maximum torque T_{max} gradually decreases to restrict the torque level (see Figs. 20(a) through 20(c)). The increase of the torque restriction rate δ_2 is set according to the time integration of the wheel speed difference ΔV since the time when the wheel speed difference ΔV exceeded the preset threshold value V_{lip} . Under the condition that the wheel speed difference ΔV becomes lower than the preset threshold value V_{lip} , after elapse of the preset cancellation time according to the driver's additional depression ΔAcc of the accelerator pedal 33, the torque restriction rate δ_2 is cancelled by the cancellation rate $\Delta\delta_2$ set corresponding to the additional depression ΔAcc of the accelerator pedal 33. The torque level is then restored to the maximum torque T_{max} (= value T4) corresponding to the updated torque restriction rate δ_2 (see Fig. 20(d)). The control procedure then cancels the torque restriction rate δ_2 in a stepwise manner to gradually restore the torque level.

As described above, like the motor control apparatus 20 of the first embodiment, the motor control apparatus of the second embodiment ensures a certain level of response to the

driver's acceleration demand, while effectively reducing the skid of the drive wheels 18a and 18b. This arrangement enhances the drivability in the skid control.

The motor control apparatus of the second embodiment

5 detects a skid based on the variation in wheel speed difference ΔV , independently of detection of a skid based on the variation in angular acceleration α by the motor control apparatus 20 of the first embodiment. The detection of a skid based on the variation in wheel speed difference ΔV may be executed only in

10 the case of no detection of a skid based on the variation in angular acceleration α or may be executed in parallel with detection of a skid based on the variation in angular acceleration α . Such modifications advantageously succeed in detecting a minor skid, which is undetectable based on the

15 variation in angular acceleration α , based on the variation in wheel speed difference ΔV . In the latter modification, in the event of detection of a skid by both the skid detection based on the angular acceleration α and the skid detection based on the wheel speed difference ΔV , the skid occurring state control

20 may refer to the map of Fig. 6, set the maximum torque T_{max} corresponding to the sum of the peak value α_{peak} [rpm / 8 msec] of the angular acceleration α set at step S152 in the skid occurring state control routine of Fig. 5 and the torque

restriction rate δ_2 [rpm / 8 msec] input at step S280 in the skid occurring state control routine of Fig. 16 ($T_{max} \leftarrow g(\alpha_{peak} + \delta_2)$), and control the motor 12 with the setting of the maximum torque T_{max} . The skid occurring state control may 5 alternatively set the maximum torque T_{max} corresponding to the greater between the peak value α_{peak} of the angular acceleration α and the torque restriction rate δ_2 and control the motor 12 with the setting of the maximum torque T_{max} . Similarly the skid convergence state control may refer to the map of Fig. 6, set 10 the maximum torque T_{max} corresponding to the grand total of the sum $(\delta_1 + \delta_{safe})$ of the torque restoration limit δ_1 set at step S176 (or input at step S170) and the torque restriction rate δ_{safe} input at step S170 in the skid convergence state control routine of Fig. 7, or the sum $(\delta_1 + \delta_{safe} + \alpha)$ of $(\delta_1 + \delta_{safe})$ 15 and the angular acceleration α when the angular acceleration α exceeds $(\delta_1 + \delta_{safe})$, and the torque restriction rate δ_2 set at step S306 (or input at step S300) in the skid convergence state control routine of Fig. 18 ($T_{max} \leftarrow g(\delta_1 + \delta_{safe} + \delta_2)$ or $g(\delta_1 + \delta_{safe} + \delta_2 + \alpha)$), and control the motor 12 with the 20 setting of the maximum torque T_{max} . The skid convergence state control may alternatively set the maximum torque T_{max} corresponding to the greater between $(\delta_1 + \delta_{safe})$ and δ_2 or between $(\delta_1 + \delta_{safe} + \alpha)$ and δ_2 and control the motor 12 with

the setting of the maximum torque T_{max} .

The embodiments described above regard control of the motor 12, which is mounted on the vehicle 10 and is mechanically connected with the drive shaft linked to the drive wheels 18a and 18b to directly output power to the drive shaft. The technique of the invention is applicable to a vehicle of any other structure with a motor that is capable of directly outputting power to a drive shaft. For example, one possible application of the invention is a series hybrid vehicle including an engine, a generator that is linked to an output shaft of the engine, a battery that is charged with electric power generated by the generator, and a motor that is mechanically connected with a drive shaft linked to drive wheels and is driven with a supply of electric power from the battery.

Another possible application of the invention is a mechanical distribution-type hybrid vehicle 110 including an engine 111, a planetary gear 117 that is connected with the engine 111, a motor 113 that is connected with the planetary gear 117 and is capable of generating electric power, and a motor 112 that is also connected with the planetary gear 117 and is mechanically connected with a drive shaft linked to drive wheels to directly output power to the drive shaft, as shown in Fig. 21. Still another possible application of the invention is an electrical

distribution-type hybrid vehicle 210 including a motor 212 that has an inner rotor 213a connected with an output shaft of an engine 211 and an outer rotor 213b connected with a drive shaft linked to drive wheels 218a and 218b and relatively rotates 5 through electromagnetic interactions between the inner rotor 213a and the outer rotor 213b and a motor 212 that is mechanically connected with the drive shaft to directly output power to the drive shaft, as shown in Fig. 22. Another possible application of the invention is a hybrid vehicle 310 including an engine 10 311 that is connected with a drive shaft linked to drive wheels 318a and 318b via a transmission 314 (for example, a continuous variable transmission or an automatic transmission) and a motor 312 that is placed after the engine 311 and is connected with the drive shaft via the transmission 314 (or a motor that is 15 directly connected with the drive shaft), as shown in Fig. 23. In the event of the occurrence of a skid on drive wheels, the torque control mainly controls the motor mechanically connected with the drive shaft, because of its high torque output response. The control of this motor may be combined with control of the 20 other motor or with control of the engine.

The embodiments and their modified examples discussed above are to be considered in all aspects as illustrative and not restrictive. There may be many other modifications,

changes, and alterations without departing from the scope or spirit of the main characteristics of the present invention.

Industrial Applicability

- 5 The technique of the invention is effectively applied to automobile and train-related industries.
